In this Letter, we discuss the effect of slow real modes in reaction-diffusion systems close to a supercritical Hopf bifurcation. The spatiotemporal effects of the slow mode cannot be captured by traditional descriptions in terms of a single complex Ginzburg-Landau equation (CGLE). We show that the slow mode coupling to the CGLE introduces a novel set of finite wavelength instabilities not present in the CGLE. For spiral waves, these instabilities highly affect the location of regions for convective and absolute instability. These new instability boundaries are consistent with transitions to spatiotemporal chaos found by simulation of the corresponding coupled amplitude equations.

PACS numbers: 47.20.Ky, 52.35.Mw

Amplitude equations have been used in a variety of scientific contexts to describe spatiotemporal oscillations in a number of chemical reaction-diffusion systems. Recently, it was shown [4] that the CGLE fails to model even qualitatively the dynamics of a realistic 4-species Oregonator model [5] of the BZ reaction. This discrepancy is caused by the presence of a slow real mode in the homogeneous part of the Oregonator model. By considering a slow-field coupling to the CGLE, we show how the inclusion of an amplitude equation for the slow mode gives rise to a finite wavelength instability for plane waves which is not present in the CGLE. For spiral waves, we have calculated new boundaries for convective and absolute instability.

Here we consider reaction-diffusion systems whose spatiotemporal dynamics is governed by

$$\frac{\partial \mathbf{c}}{\partial t} = \mathbf{F}(c; \mu) + \mathbf{D} \cdot \nabla^2 \mathbf{c},$$  

where \( \mathbf{c} = \mathbf{c}(x, t) \) depends on the spatial position vector \( x \) and time \( t \), and \( \mathbf{D} \) is a diffusion matrix. Close to the onset of a supercritical Hopf bifurcation of a homogeneous solution of Eq. (1), the spatiotemporal modulation of this state can be described by the CGLE. In dimensionless form, the CGLE can be written compactly as

$$\dot{w} = w - (1 + \imath \alpha)w|w|^2 + (1 + \imath \beta)\nabla^2 w.$$  

As shown in [3], the two real coefficients, \( \alpha \) and \( \beta \), and the transformation from \( w \) to chemical concentration \( c \) can be derived rigorously from the original reaction-diffusion system (1). The CGLE admits plane wave solutions of the form \( w(t, x) = A \exp[i(Q \cdot x - \omega t)] \), with amplitude \( A = \sqrt{1 - Q^2} \) and frequency \( \omega \) determined by the dispersion relation \( \omega = \beta Q^2 + (1 - Q^2)\alpha \) (where \( Q = |Q| \)). The stability of a given plane wave is determined by the growth rate \( \lambda(k) \) of perturbations with \( k \parallel Q \)

$$\lambda(k) = -(k^2 + 2\beta k Q + A^2)$$

$$+ \sqrt{(1 + \alpha^2)A^4 - (\beta k^2 - 2i\kappa Q + \alpha A^2)^2}.$$  

(3)

In particular, at the Eckhaus border defined by

$$D_\parallel = 1 + \alpha \beta - 2(1 + \alpha^2)Q^2/(1 - Q^2) = 0,$$  

a plane wave with given \( Q \) will be unstable to long-wavelength perturbations if \( D_\parallel(Q) < 0 \); finally, all plane waves are rendered unstable at the Benjamin-Feir-Newell (BFN) instability [6] where \( 1 + \alpha \beta < 0 \).

For simple oscillatory chemical systems, the CGLE shows an almost quantitative agreement with the spatiotemporal dynamics of the actual chemical system [7]. However, for more complicated models of the BZ reaction, we have previously described [4] how the CGLE fails even qualitatively to model characteristic time and length scales of the models. This disagreement is caused by the presence of a slow (near-critical) real mode. To incorporate the dynamics of the slow real mode into a description valid close to criticality, one may derive an amplitude equation similar to the normal form associated with a fold-Hopf bifurcation for homogeneous systems [8]. In dimensionless representation, the amplitude equations become

$$\dot{w} = w + (1 + \imath \gamma)wz - (1 + \imath \alpha)w|w|^2$$

$$+ (1 + \imath \beta)\nabla^2 w,$$  

$$\epsilon \dot{z} = \lambda_0 z + \kappa|w|^2 + \epsilon \delta \nabla^2 z,$$  

(5a)

(5b)

where \( w \) and \( z \) describe the complex and real amplitudes of the oscillatory and slow real mode, respectively. The parameter \( \lambda_0 \) is the reciprocal time scale of the slow real mode.
mode and $e$ describes the distance to the Hopf bifurcation point. Expressions relating the resonant nonlinear coefficients $\alpha_s$, $\gamma$, and $\kappa$ to Eq. (1) can be derived by application of classical normal form theory [8]. We shall refer to the system (5) as the distributed slow-Hopf equation (DSHE). A similar system of amplitude equations was derived by Riecke for description of traveling wave trains in binary-mixture convection [9]. Observe that resonant terms of the order $w^2 z^2$ in Eq. (5a) and $z^2$ in Eq. (5b) have been left out in the DSHE because these do not affect the dynamics in the part of parameter space discussed here. The DSHE may be considered as a "normal form" or prototype model for oscillatory reaction-diffusion systems with a slow real mode. It describes, for example, a realistic 4-species model for the BZ reaction very well [4]. In the adiabatic approximation where either the coefficient $a$ changes sign when $e \to 0$, we obtain that $E_\text{above}$ is the Eckhaus criterion (3) for the CGLE. For $Q = 0$, we observe that the FBN criterion also holds for the DSHE. For the DSHE, all plane waves are long-wavelength unstable when $1 + \alpha \beta < 0$. For the DSHE, this no longer holds, since a band of plane waves of finite wave number still remains stable at the BFN point when $e > -\lambda_0(\lambda_0 + \kappa)/(2\kappa(1 + \beta \gamma))$. This band of plane waves, however, can become unstable to finite wavelength perturbations determined by the condition

$$F_\parallel = \text{Re} \sigma(k) = 0, \quad |k| > 0.$$  

For example, for a homogeneous plane wave ($Q = 0$), expansion of $\sigma(k)$ to lowest nontrivial order in $e$ and fourth order in $k$ yields

$$\sigma(k) = -(1 + \alpha \beta)k^2 - \frac{i}{2}(1 + \alpha^2)\beta^2 + 2 \frac{\beta(1 + \alpha \beta - \delta)(\alpha - \gamma)\kappa}{\lambda_0(\lambda_0 + \kappa)} e|k|^4.$$  

(10)

(open circles on figure). As $\alpha$ increases, the corresponding instability curve exhibits a limit point (black circle); above this point, all plane waves are unstable. The variation along the finite instability curve of the marginally unstable wave number of the finite perturbation is shown in 2(c).

Similar to the CGLE, the DSHE admits spiral wave solutions (phase defects) in both one and two spatial dimensions. In two spatial dimensions, these may be expressed in polar coordinates $(r, \theta)$ as $w(r, \theta) = A(r) \exp[i(\psi(r) - \theta)]$ and $z(r) = Z(r)$, where $A(r)$ and $\psi(r)$ are the amplitude and phase of the spiral wave, respectively, in the complex $w$ component, whereas $Z(r)$ is the amplitude of the slow $z$ component. These three quantities must satisfy the boundary value problem

$$A(0) = \psi(0) = Z(0) = 0,$$  

$$\lim_{r \to \infty} A(r) = \sqrt{(1 - Q_0^2)/(1 + \kappa/\lambda_0)},$$  

$$\lim_{r \to \infty} Z(r) = -\lim_{r \to \infty} A(r)^2 \kappa/\lambda_0.$$  

(12)

(12)

The DSHE admits a family of plane wave solutions of the form

$$w(t, x) = A \exp[i(Q \cdot x - \omega t)], \quad z(t, x) = Z,$$  

(7)

where $A = \sqrt{(1 - Q^2)/(1 + \kappa/\lambda_0)}$, $Z = -A^2 \kappa/\lambda_0$, and the frequency $\omega$ given by the dispersion relation $\omega = \beta Q^2 + \alpha \lambda^2$ with $\alpha$ given by Eq. (6). To investigate the stability of the plane waves (7), we consider the growth rate $\sigma(k)$ of longitudinal perturbations with $k \parallel Q$. For the DSHE, an analytic equation of the spectrum of eigenvalues requires the solution of a cubic polynomial with complex coefficients, and is therefore not suitable for analytic evaluation. Instead, we may apply second-order linear perturbation theory [10] to obtain a series expansion for the growth rates: For the first-order correction to the Eckhaus criterion (4), we obtain for the DSHE

$$E_\parallel = D_\parallel + \frac{4(\alpha - \beta)(\alpha - \gamma)Q^2}{\lambda_0(\lambda_0 + \kappa)} e = 0,$$  

(8)

where $D_\parallel$ is the Eckhaus criterion (3) for the CGLE. For $Q = 0$, we observe that the BFN criterion also holds for the DSHE. For the DSHE, all plane waves are long-wavelength unstable when $1 + \alpha \beta < 0$. For the DSHE, this no longer holds, since a band of plane waves of finite wave number still remains stable at the BFN point when $e > -\lambda_0(\lambda_0 + \kappa)/(2\kappa(1 + \beta \gamma))$. This band of plane waves, however, can become unstable to finite wavelength perturbations determined by the condition

$$F_\parallel = \text{Re} \sigma(k) = 0, \quad |k| > 0.$$  

For example, for a homogeneous plane wave ($Q = 0$), expansion of $\sigma(k)$ to lowest nontrivial order in $e$ and fourth order in $k$ yields

$$\sigma(k) = -(1 + \alpha \beta)k^2 - \frac{i}{2}(1 + \alpha^2)\beta^2 + 2 \frac{\beta(1 + \alpha \beta - \delta)(\alpha - \gamma)\kappa}{\lambda_0(\lambda_0 + \kappa)} e|k|^4.$$  

(10)

(10)
where \( Q_s = \lim_{r \to -\infty} \psi'(r) \) is the unique wave number selected by the spiral wave. We now discuss the stability properties of the spiral wave solutions of Eq. (12). In order to compare the results with the properties of the CGLE, we shall use the parameter \( \alpha \) determined implicitly by Eq. (6) as the free parameter, whereas all other parameters in the DSHE (5) are kept fixed.

For large \( r \), spiral waves resemble plane wave solutions of the form Eq. (7), and we may therefore expect that the spiral wave stability is governed by the corresponding stability for a plane wave with \( Q = Q_s \). The transitions where spiral waves become either Eckhaus unstable or unstable to finite wavelength perturbations are therefore \( D_{\parallel}(Q_s) = 0 \) or \( F_{\parallel}(Q_s) = 0 \), respectively. However, as described in [11], spiral waves emit plane waves with a nonzero group velocity \( \text{Im} \partial \sigma / \partial k \). The conditions (8) and (9) guarantee convective instability only; perturbations may still drift and do not necessarily amplify at a fixed position. To determine exponential growth of a perturbation \( u(x,t) \) even in a steady coordinate frame, we must evaluate the Fourier integral

\[
    u(x,t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} u_k(0) e^{i(kx + \sigma(k)t)} dk
\]

for large \( t \) in the saddle-point approximation [12] \( u_k(0) \) denotes the Fourier transform of \( u(x,0) \). The crossing to absolute instability is then determined by the two conditions \( \sigma'(k_0) = 0 \) and \( \text{Re} \sigma(k_0) = 0 \).

For four selected values of \( \epsilon \), we have determined the variation in the \( (\alpha, \beta) \) plane of the DSHE instability thresholds for Eckhaus, finite wavelength, and absolute instability as shown in Fig. 3. To solve the associated highly unstable boundary value problem, we have used a continuation tool with support for multiple shooting [13]. The corresponding Eckhaus and absolute instability borders for the CGLE are also shown as indicated by the gray-shaded area. Even for \( \epsilon \) small 3(a), the Eckhaus threshold deviates significantly from the corresponding CGLE curve whereas the absolute instability curve almost coincides with the CGLE result. Note that the finite wavelength instability does not exist for this value of \( \epsilon \). However, as \( \epsilon \) is increased [Figs. 3(b)–3(d)], the finite wavelength curve completely determines the onset of convective instability, and the Eckhaus curve has been omitted from these panels. We observe that both of the

FIG. 3. Parameter diagrams showing the variation of the instability boundaries for spiral wave solutions of the DSHE (5) for four different values of the parameter \( \epsilon \). The figure shows the dominant boundaries for convective instabilities (dashed line), Eckhaus (EH) in (a), and finite wavelength (FN) in (b)–(d), together with the boundary for absolute instabilities (AI, solid line). The left and right boundaries of the gray-shaded area indicate the EH and AI curves for the CGLE, respectively. The Benjamin-Feir-Newell line (BFN) is also shown. For (b) and (d), small circles indicate points where the behavior has been confirmed by direct simulation of the DSHE.
The bifurcation diagram known for the CGLE as well as the Eckhaus criterion, Eq. (4), gives rise to persistent spatiotemporal chaos.

As observed for the CGLE [11,14], the absolute instability (AI) line is indicative for the onset of persistent turbulence. Numerical simulations of the DSHE indicated by dots in Figs. 3(b) and 3(d) confirm a similar observation: spiral waves are convectively unstable below the AI line and absolutely unstable above the AI line, where a transition to sustained turbulence is observed. A representative scenario for the DSHE close to the AI line in Fig. 3(d) is shown in Fig. 4.

The results derived in the stability analysis presented for the DSHE (5) show that the presence of a slow mode in oscillatory chemical reaction-diffusion systems can give rise to a finite wavelength instability of plane waves and spiral waves, which does not occur in the CGLE. In a real chemical system, this instability occurs at a value of \( e = 10^{-3} \) where the amplitude of the oscillations is just below the limit of detection. So even close to the Hopf bifurcation point, this instability completely determines the stability of plane waves [which for the CGLE is given solely by the Eckhaus criterion, Eq. (4)]. As shown in both Figs. 2 and 3, the finite wavelength instability has profound effects on the location of boundaries for convective and absolute stability for spiral waves, and completely alters the classical bifurcation diagram known for the CGLE as \( e \) is increased.

For simple model systems of oscillatory chemical reaction-diffusion systems, such as the Brusselator [15] and the Gray-Scott model [16], the CGLE provides an almost quantitative description of spatiotemporal structures even at quite large distances from the bifurcation point; however, models of realistic chemical and biochemical systems, such as the BZ reaction, the horseradish peroxidase system [17], and glycolytic oscillations [18,19] all possess one or more slow modes, and it is therefore unlikely that the CGLE will be applicable for modeling experimental observations on such systems.

We thank Lorenz Kramer for stimulating discussions and Igor Schreiber for valuable guidance with the calculation of the stability boundaries shown in Fig. 3.
